RE: Annual report under Grant No.: N000141110450

Dear Sir/Madam:

Enclosed please find our annual report under the above grant. Please let us know if you have any questions.

Yours sincerely,

Mary Morris
Contract Administrator

Enclosure: Annual report

**Investigation of the Representation of OLEs and Terrain Effects Within the
Coastal Zone in the EDMF Parameterization Scheme:
An Airborne Doppler Wind Lidar Perspective**

Annual Report
Under Grant No.: N000141110450

Covering the Period:
30 June 2013 – 30 September 2014

Submitted by:

Simpson Weather Associates, Inc.

INTRODUCTION WITH GOALS

The goal of our segment of the Unified Physical Parameterization for Extended Forecasts DRI continues from prior reporting periods to provide observations related to the partitioning of atmospheric boundary layer (ABL) fluxes into two contributions: eddy diffusivity and vertical mass fluxes (EDMF). In addition to the field campaign, the goal is to validate the existing EDMF expressions and to propose alternatives or modifications to those formalisms.

These goals are being pursued using data sets obtained from the CIRPAS Twin Otter flown in two differing regions: off the coast of California near Monterey and over portions of the Dugway Proving grounds in Utah. Data provided by UCI (Khelif) from the Controlled Towed Platform (CTV) has also been incorporated into our investigations.

OBJECTIVES

The general objective is to collaborate with NRL (Wang), UCI (Khelif) and the general numerical modeling community working with the WRF and COAMPS to use airborne sensors to probe the ABL for organizing structures such as OLEs and LLJs and, using models when appropriate, construct algorithms that would relate space-based sensor observables to the varying structure dependent ABL fluxes. Two regions have been used to collect data for the evaluation and modification of the EDMF formalisms:

1. In areas of neutral to stable ABLs capped by cloud cover ranging from zero to 100%, measure the fluxes at the air-sea interface using the TODWL and CTV instruments flown together near the California coastline in September 2012.
2. Using the MATERHORN experiment at Dugway, UT in October 2012 as an opportunity to expand the DWL data base to include ABL surveys in complex terrain as a comparison to the ABL over cold water. Note that the MATERHORN was co-funded by ONR (Ferek).

As this research has progressed, we have added a modeling component (See attachment 4) to better understand the implications of ABL structures being revealed by the TODWL during the September and October 2012 field campaigns.

GENERAL APPROACH

The work on objective one above continues as we examine several cases in 2012 where the CTV was operating adequately and the ABL contained OLEs and LLJs needed for our investigation. The first important step was to navigate the data from the two systems so that their data sets could be joined. This was not as easy as it seemed since the CTV did not fly faithfully directly below the Twin Otter. This platform relative navigation has been done and is reported in attachment 3.

The second step is to compute heat, moisture and momentum fluxes for both the CTV and Twin Otter flux sensors. The computation of fluxes from the CTV will be done by both UCI (Khelif) and SWA (Emmitt).

The third step is to determine the correlations between ABL structures and the fluxes. The end product is envisioned as being a set of PDFs for mass flux contributions as a function of regional model representations of the BL including space-based observations that can be used to infer organized structures such as LLJs (ASCAT and CALIPSO) and OLEs (MODIS, VIIRS and GEOS).

The fourth step is to evaluate several modifications to the EDMF as currently being implemented in models. These modifications would attempt to improve the representation of boundary layer roll (convective and dynamically driven) contribution to the total energy and mass fluxes.

A final effort will be made to relate the fluxes measured at flux tower sites with those measured onboard the Twin Otter during flybys. During those passes the winds and aerosols were mapped by the TODWL. These data sets will be explored for relationships between the BL organization and flux intensities.

WORK COMPLETED

In the final half of year 3/4 on this project, we have processed more than 50 hours of TODWL data from both the Monterey and DPG areas. We have combined the information from the TODWL, CTV and Twin Otter sensors to establish the relationship between the local fluxes and the energetic of LLJs and OLEs. The WRF model has been setup and run for the 7 MATERHORN missions and comparisons between the TODWL wind profiles and the model profiles have been completed for one day.

The Triad Interaction Model for OLEs has been modified by Foster to investigate “stacked OLEs” seen in the April 2007 datasets (see reported results in attachment 6)

We continue to modify the EDMF (Eddy Diffusivity and Mass Flux) parameterization to account for the differences between thermally driven convection and dynamically driven vertical transports.

Emmitt and de Wekker are using the WRF and COAMPs models to test out sensitivities to changes in the EDMF related to our field data. We have received several versions of the EDMF from Joao Teixeira for testing.

RESULTS

Most of the results of our last year’s research effort were reported at the DRI Workshop in Monterey in August 2014, the annual AGU meeting in December 2013 and at a SPIE Conference in September 2014 in Amsterdam. Five of these presentations are appended to this report:

Boundary Layer Rolls Observed Above and Below a Jet in a Marine Boundary Layer; presented at AGU 2013 by Ralph C. Foster; George D. Emmitt; Kevin Godwin; and Steven Greco

Investigating the impacts of LLJs and OLEs on ABL exchanges and transports using an airborne Doppler wind lidar; presented at AGU 2013 by G.D. Emmitt¹, R.C. Foster², K. Godwin³ and S. Greco¹

Vertical transport of TKE within Organized Large Eddies; presented at the DRI workshop 2014 by G. D. Emmitt (SWA), S. de Wekker (UVA) and R. Foster (Uwash)

EDMF in the Near-Neutrally Stratified Boundary Layer; presented at the DRI workshop 2014 by R. Foster and G. D. Emmitt

Investigation of coastal zone complex boundary circulations and their potential impact on energy transport; presented at SPIE Defense and Security Conference in Amsterdam 2014 by G. D. Emmitt, K. Godwin and R. Foster.

In addition to the presentations provided as appendices, individual reports by Ralph Foster and Stephan de Wekker are also attached. The material presented by de Wekker combines MATERHORN research results that were funded by ONR, ARO and NSF. This work lays the foundation for UPP related investigations that will be carried out in Year 4.

RELATED PROJECTS

ONR contract to study the utilization of Doppler wind lidar (DWL) data to quantify the contribution of organized large eddies (OLEs) to fluxes in the marine boundary layer (DYNAMO DRI (S. Harper, TPOC). This funded effort is now complete.

PLANS FOR YEAR 5

We have three primary goals for year 5 of this effort.

1. Finish the application of a methodology (developed last year) for joining airborne DWL data and in situ flux data to achieve an understanding of how the organized ABL structures modulate ABL fluxes.
2. Develop an expression for mass fluxes by OLEs in the MBL that is suitable for use in numerical model parameterizations. This will be derived from flux data measured directly by the CTV (Monterey) and towers (Dugway) and associated with organized ABL structures mapped from the DWL.
3. Use the COAMPS, WRF and SCM to investigate the sensitivity of these models to the ranges of values for the “MF” term as inferred from the Monterey and Dugway data sets.

We will pursue publishing our results should the findings of this research merit this effort.

Attachment 1

Boundary Layer Rolls Observed Above and Below a Jet in a Marine Boundary Layer

presented at AGU 2013

by Ralph C. Foster; George D. Emmitt; Kevin Godwin; and Steven Greco

BOUNDARY LAYER ROLLS OBSERVED ABOVE AND BELOW A JET IN A MARINE BOUNDARY LAYER

(A43A-0216)

Ralph C Foster¹, G. David Emmitt², Kevin Godwin², Steven Greco²

¹University of Washington, Seattle, WA, United States.

²Simpson Weather Associates, Charlottesville, VA, United States.

Research supported by ONR Marine Meteorology Unified Parameterization Project DRI (Dr. Ron Ferek)

Objective

- Improve physical parameterization of Atmospheric PBL processes
- Local vs. non-local fluxes of momentum, heat and water vapor
 - Convection
 - highly-skewed, very unstable stratification
- Organized Large Eddies (OLE or rolls)
 - Less Skewed, near-neutral to moderately unstable stratification
- Aircraft and towed platform observations
 - Doppler Wind Lidar to directly measure PBL structure
 - Flight-level and near-surface fluxes
- See also Poster
 - Investigating the impacts of LLJs and OLEs on ABL exchanges and transports using an airborne Doppler wind lidar (A43A-0227)

Mean wind at flight level is generally from the north

Is stacked OLE interpretation Reasonable?

- Simplify Problem:
 - Neutral stratification
 - Shear effects only
 - Omit effect of stratification above jet
 - No surface buoyancy flux
- Elevated, thin baroclinic layer
- Variable $K(z)$ (akin to MRF/YSU)
- Nonlinear stability analysis
- Floquet triad interaction

Typical Triad Solution

- Co-linear
- Based on dominant mode
- Time-dependent solution

Case Study:

- Off Monterey Bay, 30 Sep, 2012
- Prospecting DWL mode
 - ~2° forward stare
 - ~6km surface intercept from 300 m flight level
 - Line-of-Sight wind speed (VLOS)
 - Stacked VLOS ~2m vertical, 50 m horizontal resolution
 - ~0.1 m/s VLOS precision
 - ~Cross-mean-wind flight legs
- Mean state vertical profiles from Twin Otter ascent/descents
- Fluxes: see poster A43A-0227

Observations Shown "stacked OLE":

- Multiple cross-wind legs in same region
- Organized Large Eddies found throughout
- Mid-PBL wind maximum (low-level jet)
- Baroclinic mean profile (land PBL advected over the bay?)
- OLE above and below LLJ
- Sometimes connected, sometimes not
- What dynamics causes this?

Dominant mode

2nd-ary mode in above-jet layer

Conclusions

- A PBL jet can induce "stacked" OLE
- Co-linear OLE triads generate complex PBL structures
- There is a weaker, larger-scale, oblique above-jet mode
- OLE rolls are very common
 - Near-neutral
 - Low Skewness
 - Likely significant flux contribution

Attachment 2

Investigating the impacts of LLJs and OLEs on ABL exchanges and transports using an airborne
Doppler wind lidar

presented at AGU 2013

by G.D. Emmitt¹, R.C. Foster², K. Godwin³ and S. Greco¹

Investigating the impacts of LLJs and OLEs on ABL exchanges and transports using an airborne Doppler wind lidar

G.D. Emmitt¹, R.C. Foster², K. Godwin³ and S. Greco¹

¹ – Simpson Weather Associates, Charlottesville, VA, USA; ² – APL, Univ. of Washington, Seattle, WA, USA; ³ – KSG Science, Starkville, MS, USA

Objectives

- Utilize the Twin Otter Doppler Wind Lidar (TODWL) and Controlled Towed Vehicle (CTV) to take ABL wind and flux measurements over marine and coastal environments
- Extend prior investigations (2001-2008) of LLJs and OLEs in the MBL and PBLs.
- Investigate and characterize the presence of rolls (OLEs) at the boundaries of stratocumulus topped MBLs.
- Study the potential impact on the development and implementation of the EDMF into forecast models.

TODWL Data Description

Attribute	Performance Metric	Comments
LOS resolution (applies to vertical profiles of 3D winds as well)	50 m	Range resolution to hard targets (ground or dense cloud) can be better than 10 meters.
U,V,W resolution	< 10 cm/s	< 5cm/s for stationary ground based operations
Maximum range	6-30 km	Very dependent upon aerosols
Time to complete full step stare conical scan for wind profiles	~20 sec	12 point step stare with 3-2 second dwells
Sampling frequency	100 Hz	Integration of several shots is typical to improve range performance

Structure Prospecting with TODWL

- Feature prospecting uses a very shallow angle below the horizon (~ -1 -3 degrees for a 300m flight altitude).
- Results in ~ 2 m vertical resolution and 50 m horizontal resolution with ~10 meter sliding sample.
- It takes ~ 40 seconds to profile 100 meters below the aircraft.

9/30/2012 Case Study

- Processed lidar data in search of organized aerosol/wind structures below the Twin Otter
- Processed Twin Otter instrument and CTV data for time series of u, v, w, q, and θ .
- Match up times and their features from the TODWL and CABIN data sets near flight level and CTV at CTV cruise levels.

1121	288	climbing	98	.14	-1.11	-.44	.90

Summary

- The combination of an airborne Doppler Wind Lidar and a Controlled Towed Platform holds promise of a transformation of how we investigate air/sea exchanges and construct flux parameterizations for use in numerical weather models.
- This research is being funded by Dr. Ferek of the Office of Naval Research.

UPP for Extended Range Prediction

DRI Review

Monterey, CA

27 – 28 August

Objectives

- Investigate and characterize the presence of rolls (OLEs) within and at the lateral boundaries of stratocumulus topped MBLs.
- Study the potential impact on the development and implementation of the EDMF into forecast models.
- Make (or not) the case for adding an MF term unique to rolls generated by shear instabilities (non-convective).

Time to complete full step stare conical scan for wind profiles	~ 20 sec	12 point step stare with .5 -2 second dwells
Sampling frequency	100 Hz	Integration of several shots is typical to improve range performance

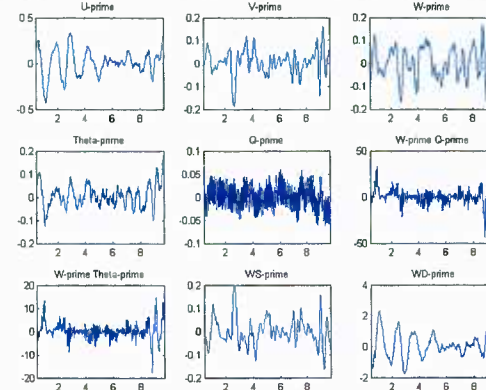

Data summary for September/October UPP field campaign with TODWL

- Three quality flights with the DWL
- One quality co-flight with the CTV (9/30).
- Two 5 hour ferry flights between Monterey, CA and Salt Lake City, Utah. (Ruby Mountain waves)
- Seven 4.5 hour flights over DPG, Utah during the MATERHORN
 - Co-funded by ONR and ARO
 - 3500 vertical profiles used to validate WRF models
 - 14 low level flights dedicated to prospecting for OLEs in the vicinity of flux towers.

Structure prospecting with DWL

- Feature prospecting uses a very shallow angle below the horizon (~ -1 - -3 degrees for a 300m flight altitude).
 - Results in ~ 2 m vertical resolution and 50 m horizontal resolution with ~ 40 meter sliding sample.
 - It takes ~ 33 seconds to profile 100 meters below the aircraft.

TODWL prospecting geometries (9/30/12)

Metric	Value
Twin Otter flight altitude	300 m MSL
Scan configuration	Straight ahead and down 1 -3°
Range gate length	50 m
Twin Otter ground speed	50 -60 m/s
Shot frequency	160/second
Shot integration (data granule)	100 (~ 40 meters forward motion)
Vertical increment between granules	~2 m
Time to sample 100 m vertical	~ 33 seconds

Idealized rolls

Spectral analyses of TODWL data

The TODWL is a 2 micron, eyesafe Coherent detection lidar. The returning Signal is heterodyned with a local optical Oscillator and then digitized (200 MHz). An FFT is used to process the resulting Time series with 50m line-of-sight Resolution. In homogeneous flows, a single Spectral feature (top figure) is identified as the frequency representation of the radial wind speed.

When probing a turbulent and/or highly Sheared environment, the spectral Feature is broadened. It is this broadening That we desire to use for estimating Turbulence on scales of 25 -100 meters With multipulse integrations over 50 - 200

Current Findings

- Columns of “spectral broadening (SB)” seen only in zones of near surface convergence and inferred upward motion
- Not all columns terminate at elevated turbulence “blobs” or accumulation pockets.
- Number of SB columns per 1km is the same as the number of convergence zones. However, the spacing between convergence zones varies.

Line density of rolls (per 10 km)

Flight Segment	SB Columns	Horizontal Convergence zones

Summary (Marine)

- The combination of an airborne Doppler Wind Lidar and a Controlled Towed Platform holds promise of a transformation of how we investigate air/sea exchanges and construct flux parameterizations for use in numerical weather models.
- Interpretation of the TODWL derived spectral width is a primary focus of our current investigation.
- Presentation by Foster this afternoon will address the second focus area, that of adding a “shear instability driven rolls” term to the EDMF.

Rolls over land

- Extension of the UPP (Marine) study of rolls contribution to the EDMF to investigations over land.
- Used to provide comparisons of the roll phenomena as measured by an Airborne Doppler Wind Lidar.
- Flights conducted along Salinas Valley and over the Dugway Proving Grounds, Utah.

LOS Velocity 092512 160205 Az. Range: 37.6 to 41.8 El. Range: -1 to 2.1

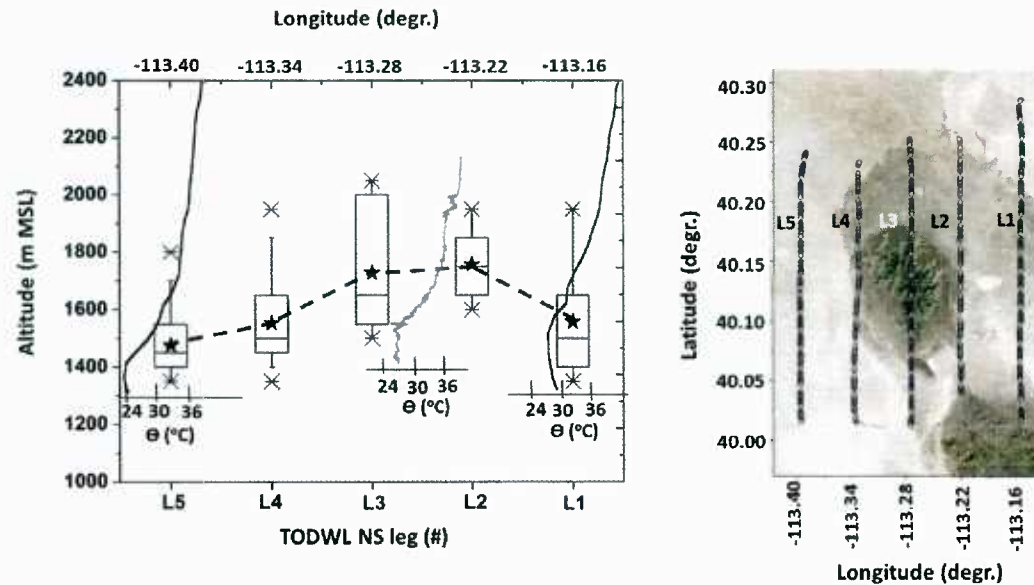

SNR

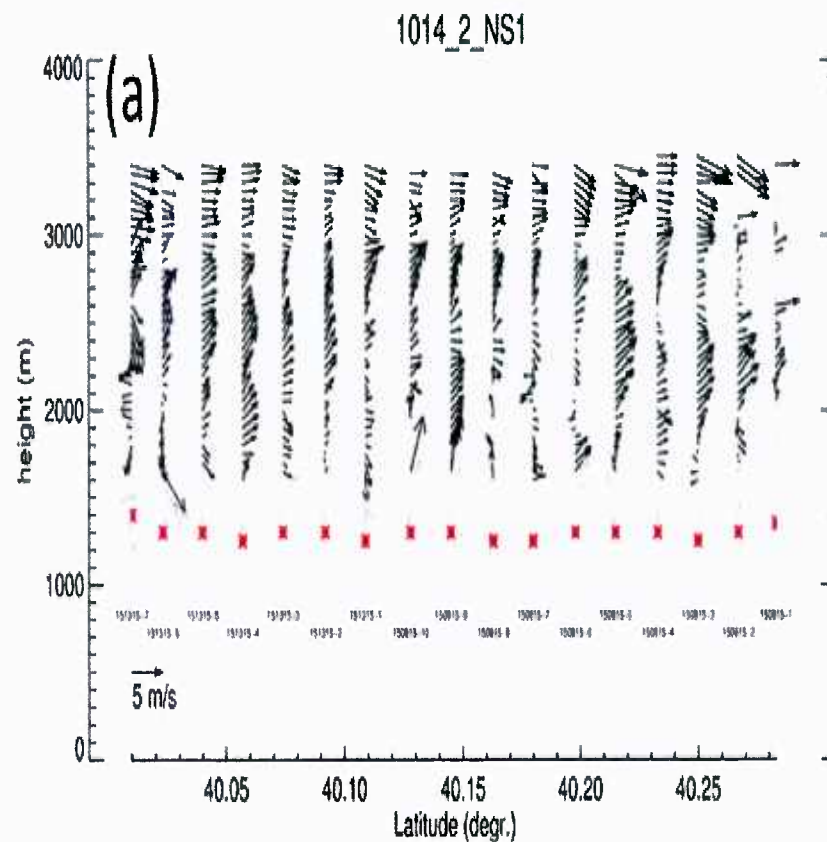

Spectral Width

Distance (m)

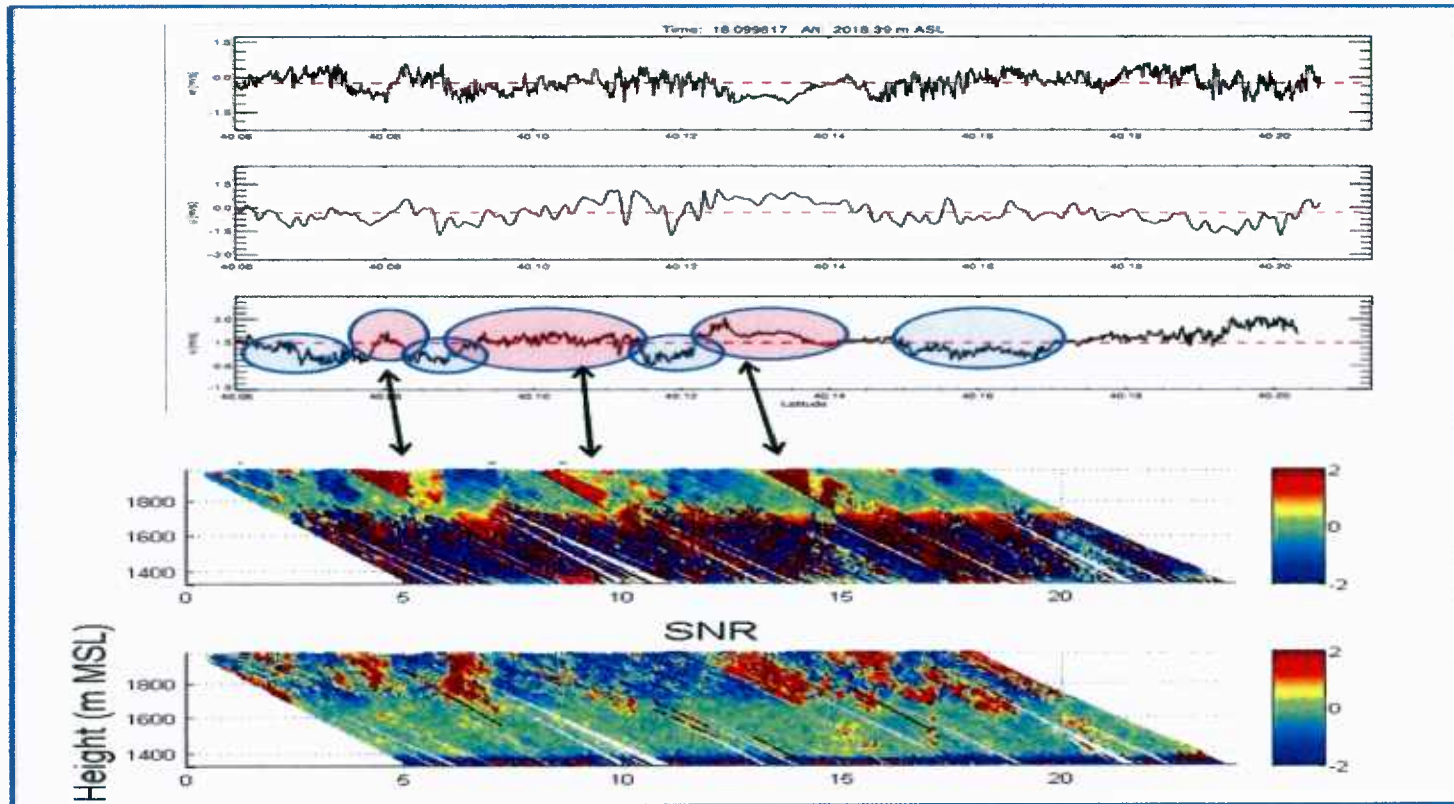

Box-and-whisker plot of the PBL heights derived from aerosol backscatter profiles along the north-south flight legs (b) performed during a morning TODWL mission between 1012 and 1052 MDT on 10 October 2012. The horizontal line in the box and the bottom and top line of the box show the median of the data, and the lower and upper quartiles (25% and 75%), respectively. The whiskers show the minimum and maximum values while the solid star is the mean value. Vertical potential temperature profiles obtained over the Playa and Sagebrush sites are shown on the western and eastern part of the domain. Also shown is the potential temperature profiles obtained from DATAHAWK (UAV) measurements located between TODWL legs L2 and L3.

Vertical profiles of TODWL derived wind speed and direction along a north-south flight leg east of Granite Peak (a) and an east-west flight leg over Granite Peak (b) on the afternoon of 14 October 2012.

From top to bottom, horizontal profile of turbulence kinetic energy, vertical velocity vat two heights, and topography below a flight leg east of Granite Peak on 14 October 2012

From top to bottom: w , u , and v –wind component along a flight leg east of Granite peak on 14 October 2012. The flight leg shown here is about 10 km further to the east than the flight leg shown in Fig. 3. Shown in the bottom two panels are the line of sight velocity and the signal-to-noise ratio of a forward stare on the same flight leg. In these panels, coherent turbulence structures are visible that align well with velocity fluctuations from the in-situ aircraft measurements.

Summary (land)

- Both convective and shear driven rolls can be seen over land in the daytime.
- Salinas Valley exhibits convective rolls in the daytime and shear driven rolls at night (not discussed in this presentation).
- Deeper boundary layers at DPG exhibit rolls but are difficult to characterize in any detail.

Presentations and Students

- Two graduate students supported at UVA. Focused upon the DPG data sets.
- Papers presented at multiple working groups, AGU 2013, SPIE 2014, AMS 2013, 2014.
- Paper to be published on the 9/30 case study on hold until sampling modeling is complete.

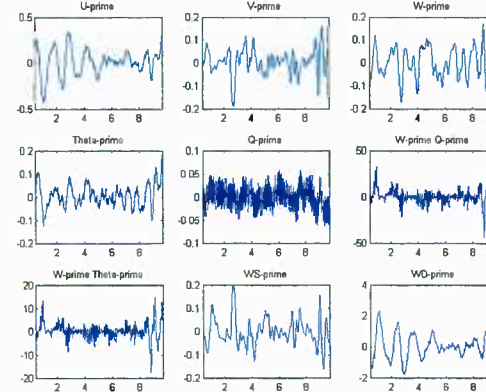

Research Plans

- Complete DWL sampling model developed to understand the impact of various scales of turbulence and shear on spectral broadening.(Emmitt and O'Handley)
- Reprocess the 9/30/12 data sets guided by input from the sampling model.(Emmitt and Godwin)
- Extend Foster model to cover the various modes of the MBL (Ri , shear, convective stability) (Foster)
- Conduct sensitivity experiments with a modified EDMF within the WRF and perhaps, the COAMPS. (de Wekker and Foster).
- Produce a lessons learned document and draft plan for an intensive TODWL/CTV investigation of non-convective rolls. Interact with the roll investigators (Mahrt, Ginis, ..) in the design.

EDMF in the Near-Neutrally Stratified Boundary Layer

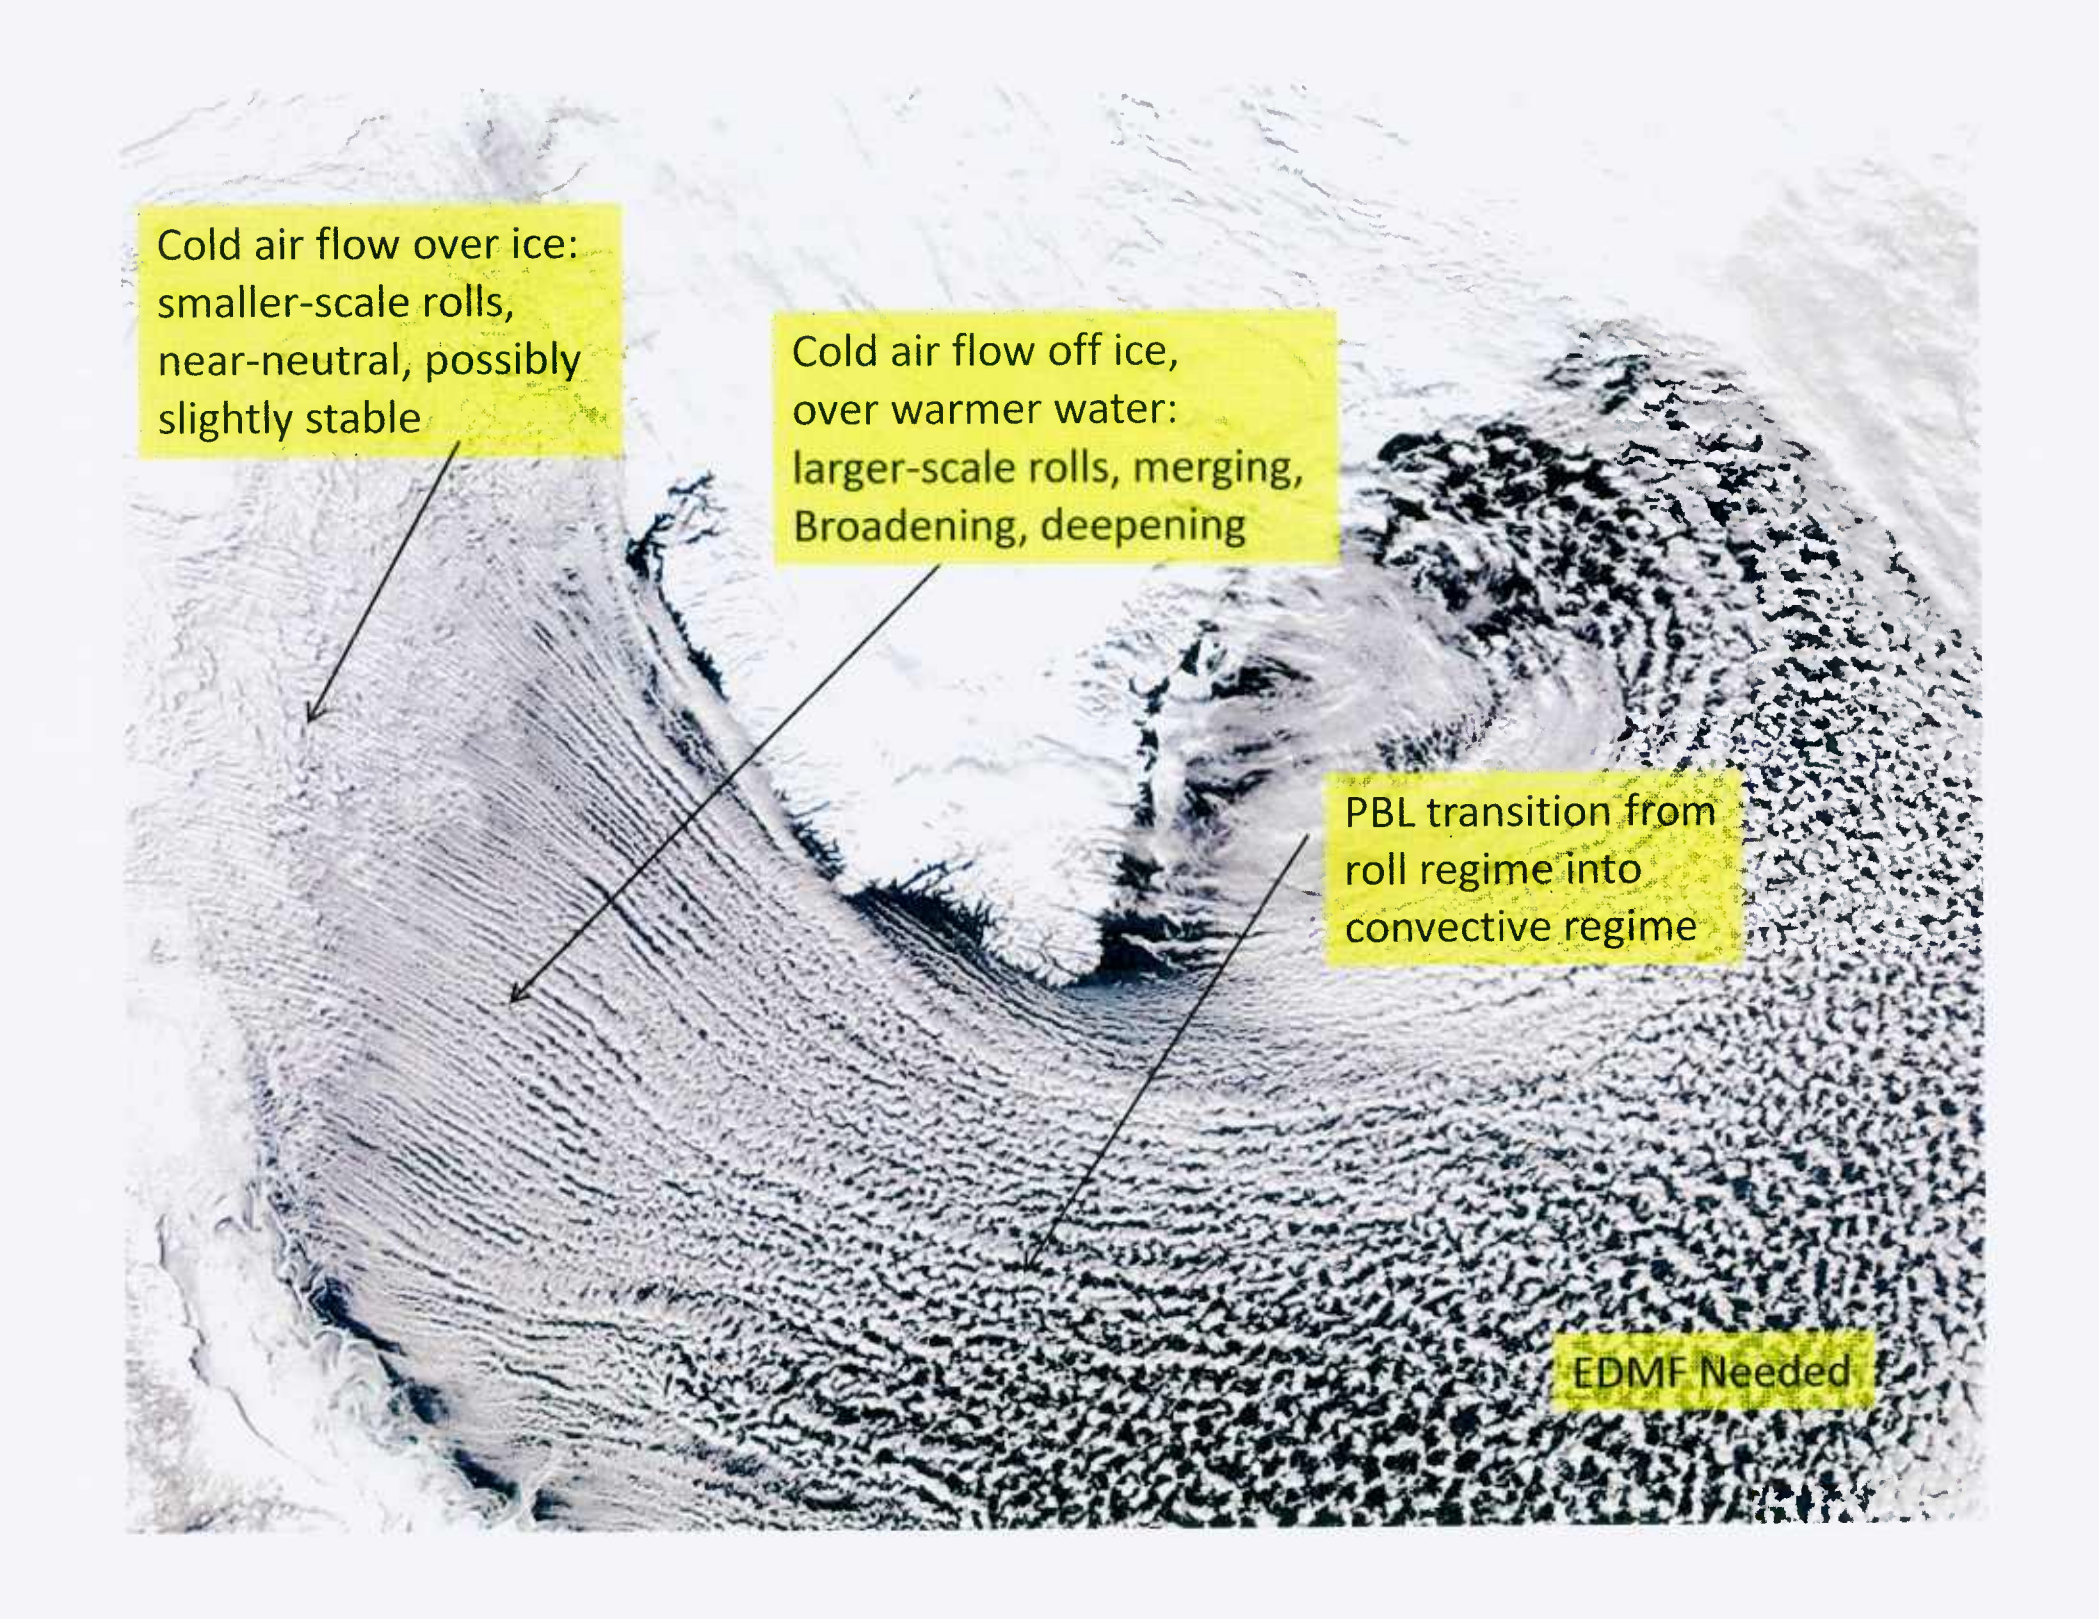

presented at the DRI workshop 2014

by R. Foster and G. D. Emmitt

EDMF in the Near-Neutrally Stratified Boundary Layer

Ralph Foster, APL UW

G. David Emmitt, SWA

Cold air flow over ice:
smaller-scale rolls,
near-neutral, possibly
slightly stable

Cold air flow off ice,
over warmer water:
larger-scale rolls, merging,
Broadening, deepening

PBL transition from
roll regime into
convective regime

EDMF Needed

EDMF

- Method for estimating the non-gradient contribution to the PBL fluxes
- Current MF focus is on non-gradient contribution in low winds, primarily buoyancy production
 - Assumes ED model correctly models PBLs with significant shear production
- Does EDMF need to capture the non-gradient fluxes due to roll OLE?
 - Extension of MF contribution to near-neutral stratification

PBL Rolls

- Very common
 - Span the depth of the PBL
 - Due to combined shear & convective instability
 - $U_{10} > \sim 5$ to 7 m/s
 - Near-neutral to moderately unstable stratification
 - Non-gradient diffusion transport
 - Is this contribution important?
 - Can we measure it?
 - Can we parameterize it?

Simulation and parameterization of the turbulent transport in the hurricane boundary layer by large eddies

Ping Zhu¹

Received 27 November 2007; revised 31 March 2008; accepted 23 May 2008; published 3 September 2008

[1] Hurricane boundary layer (HBL) processes, especially the structure of the coherent large eddy circulations (LECs) and their induced vertical transport, are not well understood. This paper introduces a large eddy simulation (LES) framework in a weather hindcasting mode developed from a multiple scale nested Weather Research and Forecasting (WRF) model. Using the WRF-LES, this study investigated the structure of the HBL LECs and the associated vertical transport during the landfall of Hurricane Ivan (2004). The simulation shows that the HBL LECs exist in a mean stable environment and consist of well-defined updraft and downdraft. Statistically, the HBL LECs are only slightly skewed with the updrafts and downdrafts relatively evenly distributed spatially.

ZHU: HURRICANE BOUNDARY LAYER TURBULENT TRANSPORT

Figure 5. Histogram of the distance between the cores of maximum and minimum winds in the surface wind bands.

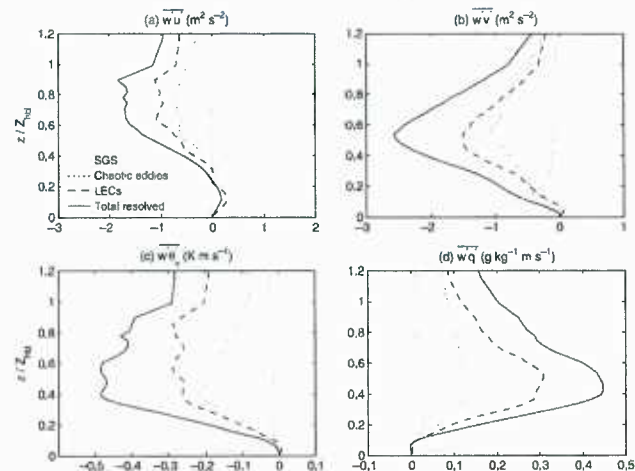

Figure 6. Flux profiles of resolved turbulent eddies and SGS turbulence averaged over the landfall period from 05:00 UTC to 08:00 UTC. Black solid: total resolved fluxes; dashed: fluxes induced by the HBL LECs; dotted: fluxes generated by chaotic turbulent eddies. Light solid: fluxes of SGS turbulence. The height has been normalized by the mean HBL height, which is defined as the base of the inversion layer.

ZHU: HURRICANE BOUNDARY LAYER TURBULENT TRANSPORT

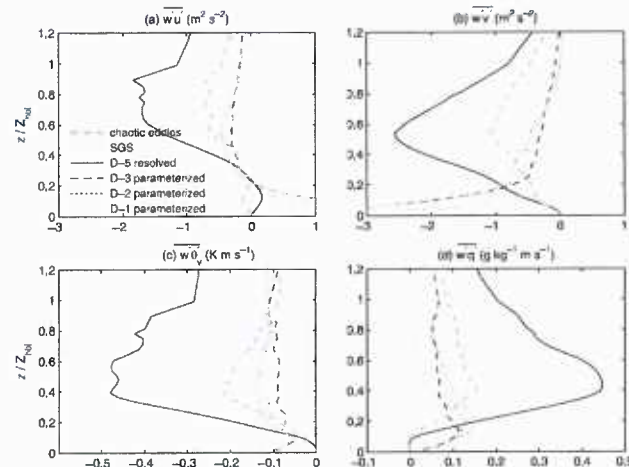

Figure 9. The resolved and SGS turbulent fluxes in D-5 averaged over the landfall period from 05:00 UTC to 08:00 UTC compared with the parameterized turbulent fluxes at the location in D-1, D-2, and D3 where D-5 is nested. The dark solid and the light dot-dashed profiles indicate the total resolved and SGS fluxes in D-5, respectively. The light thick dashed profile indicates the contribution from the resolved chaotic eddies only. The light solid, light dotted, and dark dashed profiles are the parameterized turbulent fluxes from domains D-1, D-2, and D-5 at the grid point where D-5 is nested, respectively.

Figure 12. (a) Skewness of LECs averaged over the landfall period from 05:00 UTC to 08:00 UTC. (b) The mean spatial fraction of updraft over the same period.

Future work

Modify triad code for non-co-linear
OLE

*(2014: Done, preliminary look
shows highly complex roll OLE)*

Include stratification and thermal
wind effects on OLE

(2014: Done, untested)

Rolls in EDMF Framework

- Simple MBL conditions
- Look at basic co-linear triads
- Simple MF statistics
 - w' Skewness
 - Updraft fraction (σ)
 - Large-eddy mass flux ($\sigma(1 - \sigma)(w_{up} - w_{dn})$)
- Compare with previous work (Zhu, 2007)
- Compare with Observations

Basic PBL flow
(Compared to
pure Ekman)

$\lambda_\alpha = 6.61$ (ND); $\lambda_\beta = 12.57$ (ND); $\lambda_\gamma = 13.96$ (ND)
 W (shading) and ψ (contour); time = 1275 (ND)

U^\perp (shading) and ψ (contour)

For this triad, statistics vary little with time

$$w'v'$$

Discussion

- Idealized (nonlinear, triad interaction) roll OLE model produces results qualitatively similar to WRF-“LES” of hurricane PBL LEC effects
 - Similar LEC skewness and updraft fraction
 - LEC contribution much larger than PBL parameterization
- Differences with Monterey Bay lidar observations
 - Flux data suggested negative skewness near top of OLE
 - Obs suggest OLE effect on fluxes not as large as modeled
 - (10 to 30%, not half or more)
 - Lateral mixing missing in model?
 - Direct OLE effect may overestimate contribution; “collection” of turbulent eddies may be more important
 - Low-order truncation exaggerates fluxes

Low-Order Truncation Errors

Mean-flow Modification

Amplitude Estimation

Low-order truncation problems:

- Over-estimated amplitude
- “S-shaped” MF modification

Standard Non-Linear Single-Wave PBL Roll Model

 \end{aligned}$$

$\phi = \theta_A - \theta_B - \theta_C$

- **YELLOW**: contributions from single-wave theory; e.g. $q_{2,\alpha} = q_{11,\alpha}$.
- **BLUE**: new wave-wave & wave-mean flow interaction contributions.
- **RED**: Low-order phase-coupling terms.
- Also: mean-flow modifications due to each wave.

Similar triad generates different OLE effect

More similar to Obs,
Less similar to WRF-"LES"

- For this triad, statistics do vary with time
- Hurricane is very high shear, ideal for roll OLE, strongly forced modes.
- Monterey Bay had more variable conditions & layered PBL structure.

What Do We Need From Observations?

- Need to constrain parameter space
 - PBL profiles throughout roll prospecting region
 - For given mean flow (U, V, T, q), what are the characteristics of the rolls? (wavelength(s), orientation, strength)
 - Can we characterize in terms of Ri , Re , ...?
- Effects of rolls on fluxes:
 - Fluxes and flux statistics at multiple levels
 - Sfc, mid-PBL, Upper levels
 - Separate local from LEC flux contributions

Next Steps

- Investigate stratification effects & 3-D effects
- Use observations to correct model
- Implement simple roll MF addition to EDMF model

Attachment 5

Investigation of coastal zone complex boundary circulations and their potential impact on energy transport

presented at SPIE Defense and Security Conference in Amsterdam 2014
by G. D. Emmitt, K. Godwin and R. Foster.

Investigation of coastal zone complex boundary circulations and their potential impact on energy transport

G. D. Emmitt and K. Godwin
Simpson Weather Associates, Inc.

R. Foster
University of Washington

SPIE Amsterdam 2014

Objectives

- Investigate and characterize the presence of rolls (OLEs) within and at the lateral boundaries of stratocumulus topped Marine Boundary Layers (MBLs).
- Study the potential impact on the development and implementation of the Eddy Diffusivity and mass Flux (EDMF) parameterization into weather forecast models.
- Make the case for adding an MF term unique to rolls generated by both convective and shear instabilities.

TODWL

Twin Otter Doppler Wind Lidar

CTV

Controlled Towed Vehicle

TODWL data description

Attribute	Performance Metric	Comments
LOS resolution (applies to vertical profiles of 3D winds as well)	50 m	Range resolution to hard targets (ground or dense cloud) can be better than 10 meters.
U,V,W resolution	< 10 cm/s	< 5cm/s for stationary groundbased operations
Maximum range	6 -30 km	Very dependent upon aerosols
Time to complete full step stare conical scan for wind profiles	~ 20 sec	12 point step stare with .5 -2 second dwells
Sampling frequency	100 Hz	Integration of several shots is typical to improve range performance

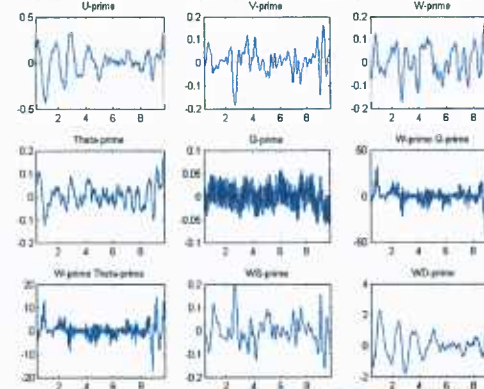

Data summary for September/October UPP field campaign with TODWL

- Three quality flights with the DWL
- One quality co-flight with the CTV (9/30).
- Two 5 hour ferry flights between Monterey, CA and Salt Lake City, Utah. (Ruby Mountain waves)
- Seven 4.5 hour flights over DPG, Utah during the MATERHORN
 - Co-funded by ONR and ARO
 - 3500 vertical profiles used to validate WRF models
 - 14 low level flights dedicated to prospecting for OLEs in the vicinity of flux towers.

Structure prospecting with DWL

- Feature prospecting uses a very shallow angle below the horizon (~ -1 - -3 degrees for a 300m flight altitude).
 - Results in ~ 2 m vertical resolution and 50 m horizontal resolution with ~ 40 meter sliding sample.
 - It takes ~ 33 seconds to profile 100 meters below the aircraft.

TODWL prospecting geometries (9/30/12)

Metric	Value
Twin Otter flight altitude	300 m MSL
Scan configuration	Straight ahead and down 1 -3°
Range gate length	50 m
Twin Otter ground speed	50 -60 m/s
Shot frequency	160/second
Shot integration (data granule)	100 (~ 40 meters forward motion)
Vertical increment between granules	~2 m
Time to sample 100 m vertical	~ 33 seconds

Idealized rolls

Convergence

Divergence

Spectral analyses of TODWL data

The TODWL is a 2 micron, eyesafe Coherent detection lidar. The returning Signal is heterodyned with a local optical Oscillator and then digitized (200 MHz). An FFT is used to process the resulting Time series with 50m line-of-sight Resolution. In homogeneous flows, a single Spectral feature (top figure) is identified as the frequency representation of the radial wind speed.

When probing a turbulent and/or highly Sheared environment, the spectral Feature is broadened. It is this broadening That we desire to use for estimating Turbulence on scales of 25 -100 meters With multipulse integrations over 50 - 200

LOS Velocity 093012 102845 Az. Range: -7 to -6 El. Range: -3 to -2

Current Findings

- Columns of “spectral broadening (SB)” of the DWL return are seen only in zones of near surface convergence and inferred upward motion
- Not all columns terminate at elevated turbulence “blobs” or accumulation pockets.
- Number of SB columns per 1km is the same as the number of convergence zones. However, the spacing between convergence zones varies greatly.

Line density of rolls (per 10 km)

Flight Segment	SB Columns	Horizontal Convergence zones
1007	25	25
1017	42	42
1028	30	30
1106	28	28
1111	16	16
1121	26	26

Summary

- The combination of an Airborne Doppler Wind Lidar and a Controlled Towed Platform holds promise of a transformation of how we investigate air/sea exchanges and construct flux parameterizations for use in numerical weather models.
- Interpretation of the TODWL derived spectral width is a primary focus of our current investigation.
- We are now focused on adding a “convective/shear instability driven rolls” terms to the EDMF.

Attachment 6

Triad Interaction Model and its role in modifying the EDMF parameterization to include contributions from non-gradient fluxes due to rolls.

Sub report

R. Foster

Triad Interaction Model and its role in modifying the EDMF parameterization to include contributions from non-gradient fluxes due to rolls.

Ralph Foster

An important part of our project is to use the Doppler wind lidar (DWL) data to guide in the development of a parameterization of roll OLE contributions to the PBL fluxes. The target for this parameterization is the eddy diffusivity/Mass flux (EDMF) PBL parameterization. As currently implemented, the EDMF parameterizes the non-gradient fluxes that are induced by convective plumes using a mass flux scheme. The plume contribution parameterization is based LES of shear-free convection. However, when shear is important, and even into the very near-neutral stratification regime, the dominant form of non-gradient fluxes is due to roll OLE, which are much more challenging to study and parameterize using LES.

For example, an EDMF model must be capable of capturing complex PBL transitions such as in off-ice flow in high latitudes. The PBL is slightly stable over pack ice, yet rolls are observed in this regime. Over water, that flow gains significant surface buoyancy flux and the rolls strengthen, broaden and deepen. Farther off-shore, they experience an up-scale transition and ultimately break down into $O(25-50 \text{ km})$ convection. At present, the EDMF parameterizes the small-scale, largely shear-driven small-scale turbulence with the ED part and the convective regime after the rolls break down. However, in the near neutral stable and the moderately unstable regimes where rolls are present, the EDMF model has no mechanism for parameterizing their non-gradient contribution to the PBL fluxes.

Our strategy is to use the DWL observations to calibrate and validate a general model for roll OLE that can be used to develop a roll parameterization for the EDMF. Roll OLE, which are often mischaracterized as either convective rolls or shear rolls are in general due to a *combined* shear and convective instability that reaches a quasi-equilibrium state in which finite amplitude rolls are maintained in a slightly modified mean state. This mechanism is well-established in the literature, most recently for the hurricane boundary layer by Foster (2005), Zhu (2008) and Nakanishi and Niino (2012). However, both our DWL observations and the numerical modeling indicate that single-mode rolls, while capturing the basic OLE flow, are insufficient to describe the variability in the PBL.

As previously reported, the general, nonlinear “single-mode” model described in Foster (2005) has been expanded to capture the nonlinear energy transfer among resonant triads of PBL modes. Resonant triads are the fundamental building blocks of the nonlinear interactions between fluid motions at different scales. Energy transferred from motions of different spatial scales into or out of a particular mode comes from modes whose wave vectors form a triangle with the wave vector for the mode in question (Fig. 1). The standard single-mode nonlinear stability analysis (e.g. Foster. 2005) will thus omit these “wave-wave interaction” pathways by which energy can flow from the dominant mode into more slowly-growing modes. Our first effort worked on the much simpler case in which the triad modes are all colinear.

In this year, we significantly expanded the model to include the nonlinear interactions between non-colinear triads. The quasi-equilibrium solutions continue to change with time, but through a limited flow regime. And at any particular time, the solutions vary spatially. The solution space is complex, but so far the results are realistic and appear to agree with simpler models (e.g. Dubos et al., 2008). A snapshot of a particular solution is shown in Figs. 2 and 3. The dominant roll OLE are oriented about 19° from the down-wind direction. The triad includes a smaller-scale mode oriented about 17° from the dominant mode and a larger-scale mode about 46° from the dominant mode. The overturning circulation induced by the roll OLE is best seen in the x-z cross-sections taken at different down-roll positions (Fig. 2). The variability in the overturning circulation strength and shape is evident, which can be seen most clearly in the vertical velocity. The along-roll velocity also varies in strength along the rolls. Fig. 3 shows the horizontal perturbation wind vectors at near the surface and in the mid-PBL. near the surface, the along-roll component dominates. In the mid-PBL, the overturning circulation dominates. The roll circulation is clearly three-dimensional and varies in both time and space. Efforts in this year will focus on understanding the non-colinear triad interactions in this simple case. This study is an important advance in PBL roll theory and is worthy of publication. Once the new (and more complex) mathematics is more carefully checked and better understood, it will be applied to the DWL observations.

Zhu (2008) proposed that roll OLE fluxes could be parameterized using the mass-flux paradigm. A key difference is that standard mass flux modeling assumes that the vertical velocity is highly skewed with a small updraft fraction. For roll OLE, the vertical velocity is only slightly skewed and the updraft fraction is closer to 50%. For a single roll OLE situation, the skewness, updraft fraction and mass flux, $(1-\sigma)(w_{up}-w_{dn})$, are all well behaved and similar to the calculations in Zhu (2008) (Fig. 4 and 5). As shown, OLE roll fluxes are inconsistent with eddy-diffusivity modeling. However, the mass flux parameterization is relatively well-behaved.

In support of the application to the EDMF, we applied the colinear triad interaction model to the OLE observations over Monterey Bay. Previously, we made a case that the mean PBL structure was likely due to advection of over-land PBL air over the thin marine layer in the bay. The mean flow indicated an elevated PBL jet at the intersection between the air masses. The observations showed a likely “stacked-OLE” configuration in which OLE were separately generated in each layer and interacted across the jet. The triad model showed greater and lesser interaction between the layers above and below the jet that varied in spatially and temporally, which was consistent with the observations (Fig. 6). Note the change in the Skewness profiles above the level of the mid-PBL jet.

In this case, consistent with the DWL data, Twin Otter fluxes and towed platform fluxes, the OLE-induced skewness is much more complex. Understanding and modeling correctly this process will be a focus in the upcoming year. In particular, we will need to implement the non-colinear roll OLE model and apply it to the Monterey PBL conditions.

Joao Teixeira’s research group at JPL has provided us with an implementation of the EDMF PBL model that we can use to experiment with implementing the OLE MF contribution.

Figure 1: Typical non-colinear roll OLE triad for simple PBL mean flow. Contours show the instability growth rate. Dominant mode is labeled B. Sub-modes are A and C. Construction shows that $A = B + C$ as required.

Figure 2: Cross-sections in the x-z plane at two locations along the dominant roll mode direction (mode B from Fig. 1). Upper panels color shading show vertical velocity. Lower panels color shading shows along-mode B OLE perturbation velocity. Vectors show the overturning circulation (U, W) perpendicular to the mode B OLE axes.

Figure 3: Horizontal cross sections (x-y) through the vertical velocity. Left panel is nearer the surface and right panel is at the mid-PBL. Vectors show the along-across horizontal velocities. Near the surface, the along-mode B component dominates. In the mid-PBL, the overturning component begins to dominate. The secondary circulation due to rolls is three-dimensional.

Figure 4: Upper panel pair: Snapshot of colinear roll OLE triad solution for a simple PBL mean flow. Upper shows vertical velocity and overturning stream function. Lower shows along-roll perturbation velocity. Lower left panel: updraft fraction. Lower right panel: vertical velocity skewness.

Figure 5: Example across-roll momentum flux. Upper panel, wu velocity product with overturning streamfunction contoured. Lower left: effective eddy viscosity needed if these fluxes are modeled using the eddy diffusivity approach. Lower right, momentum flux modeled using mass flux approach.

Figure 6: Upper panels: two snap shots of the vertical velocity for the nonlinear, colinear triad model for a mean flow profile similar to the DWL observations over Monterey Bay, 2012. Lower left: mean flow profile used to generate the solution show in the upper panels. Lower right: vertical velocity skewness from the triad model. Note that the skewness can be either positive or negative near the surface, which is consistent with the observations.

Subcontract report for Simpson Weather Associates regarding the ONR DRI project:

Investigation of the representation of OLEs and terrain effects within the coastal zone in the EDMF parameterization scheme: an airborne Doppler wind lidar perspective.

Stephan F.J. De Wekker
University of Virginia

Reporting period: 1 July 2013-30 June 2014

The planned tasks for year 3 of this project that involved subcontractor UVA were:

Task 3.1 – Processing and analysis (including algorithm and software development) of new TODWL data after completion of field program

Task 3.3 – Analysis of turbulence obtained from the standard instruments on the Twin Otter

Task 3.7 – Analyze TODWL data and compare with Radiosonde data (UVA and SWA)

Accomplishments:

During year 3, a majority of the effort was in the analysis of TODWL research flights. The UVA contribution was focused on investigating of turbulence and boundary layer structure over land, in particular during the ONR funded MATERHORN field campaign. Seven research flights in total were conducted during the MATERHORN field campaign.

We analyzed PBL heights from the TODWL data for all research flights. An example of the results for five flight legs oriented north-south for the morning of 10 October 2012 is shown in Fig. 1. A terrain following PBL height is evident with maximum heights up to about 2000 m. The TODWL derived PBL heights compare well with PBL height derived from temperature profiles from radiosonde and unmanned aerial vehicle measurements.

A typical feature of the boundary layer structure around Granite Peak is the presence of layers with large amounts of shear in wind speed and direction. We hypothesize the presence of these layers play an important role in modulating turbulence intensities and turbulence structures. An example is shown for the afternoon of 14 October 2012 for a north-south oriented flight leg east of Granite Peak. In a layer below the PBL height at around 2200 m, there was large shear in wind speed and direction, especially on the northeastern part of Granite Peak (Fig. 2). In situ measurements from the Twin Otter aircraft indicate enhancement of turbulence kinetic energy on the northern part of this flight leg (Fig. 3). The low level Twin Otter flights were designed to prospect for organized convective structures and for quantifying vertical heat and momentum fluxes associated with these structures. Forward stares from the lidar indicate the presence of organized structures that align well with the in-situ turbulence measurements (Fig. 4)

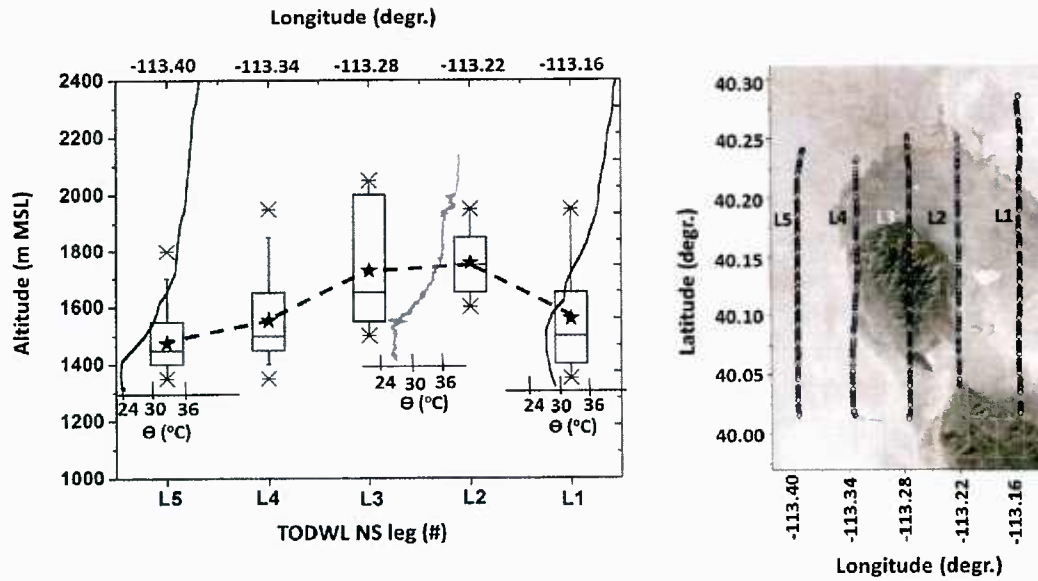

Figure 1: (a) Box-and-whisker plot of the PBL heights derived from aerosol backscatter profiles along the north-south flight legs (b) performed during a morning TODWL mission between 1012 and 1052 MDT on 10 October 2012. The horizontal line in the box and the bottom and top line of the box show the median of the data, and the lower and upper quartiles (25% and 75%), respectively. The whiskers show the minimum and maximum values while the solid star is the mean value. Vertical potential temperature profiles obtained over the Playa and Sagebrush sites are shown on the western and eastern part of the domain. Also shown is the potential temperature profiles obtained from DATAHAWK (UAV) measurements located between TODWL legs L2 and L3.

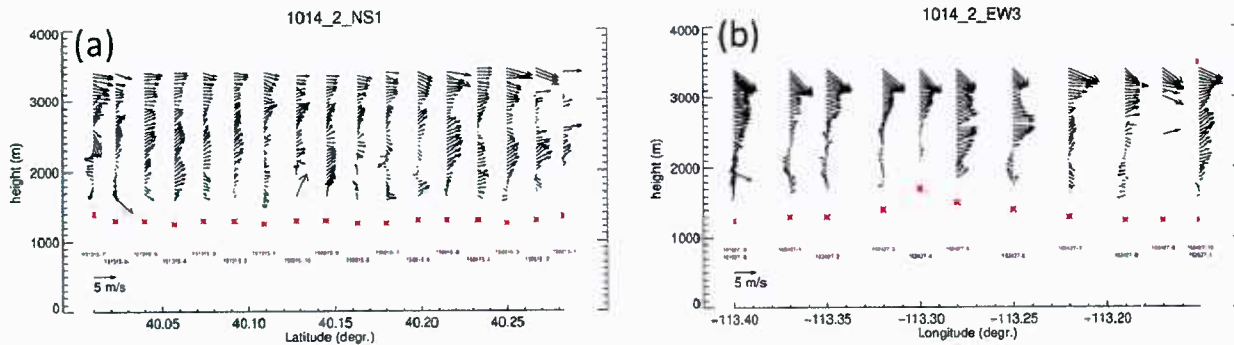

Figure 2: Vertical profiles of TODWL derived wind speed and direction along a north-south flight leg east of Granite Peak (a) and an east-west flight leg over Granite Peak (b) on the afternoon of 14 October 2012.

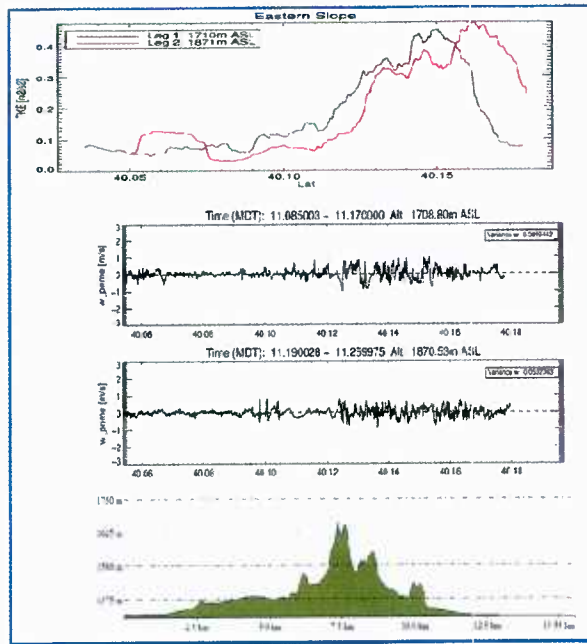

Figure 3: From top to bottom, horizontal profile of turbulence kinetic energy, vertical velocity w at two heights, and topography below a flight leg east of Granite Peak on 14 October 2012

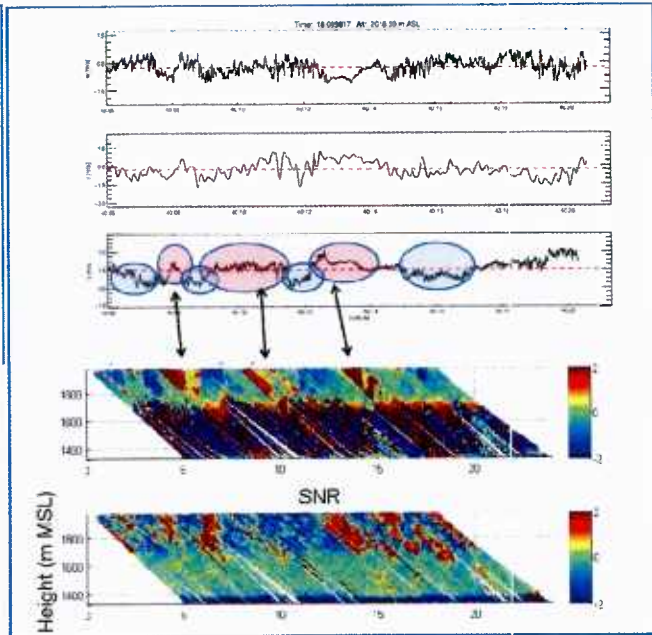

Figure 4: From top to bottom: w , u , and v —wind component along a flight leg east of Granite peak on 14 October 2012. The flight leg shown here is about 10 km further to the east than the flight leg shown in Fig. 3. Shown in the bottom two panels are the line of sight velocity and the signal-to-noise ratio of a forward stare on the same flight leg. In these panels, coherent turbulence structures are visible that align well with velocity fluctuations from the in-situ aircraft measurements.

These coherent turbulence structures are sub-grid scale for regional to global scale models and therefore one would expect an EDMF based parameterization scheme to represent the effects of these structures on the turbulent transport. We are currently collaborating with Dr. James Doyle at NRL in the use of the COAMPS to simulate these MATERHORN case studies. Doyle's group has now implemented the EDMF scheme in COAMPS and will perform simulations for one of the intensive operational periods during MATERHORN. Simulations will be done with and without EDMF parameterization at horizontal grid spacing of 4,3,2, and 1 km in the innermost domain with the overall goal to evaluate the sensitivity of the simulations to ED and MF parameters in the EDMF parameterizations. PBL structure and the simulated fluxes of heat and momentum in the PBL will be compared against the in-situ and lidar measurements from the Twin Otter flights. In addition, De Wekker has continued a collaboration with the Research Application Laboratory at the National Center for Atmospheric Research (NCAR-RAL – Knievel and Liu) to perform 'very large eddy simulations' (VLES) with a 300 m grid spacing for the various days of the research flights. Idealized simulation have also been performed in collaboration with the University of Vienna (Serafin). Output will in the next year be analyzed to detect the presence of coherent structures similar as in the observations and quantify their effect on turbulence fluxes. The general question we will investigate is whether the effect of these structures are properly represented in an EDMF based PBL parameterization.

A post-doc (Sandip Pal) and a graduate student (Mark Sghiatti) at UVA will contribute to the analysis of the model output and comparisons with observations during the next year. Graduate student Mark Sghiatti successfully defended his Master thesis proposal entitled "Spatial Variability of Turbulent

Kinetic Energy and Turbulent Fluxes around an Isolated Mountain”. He is expected to graduate in fall 2015.

Approved for Public Release, distribution is Unlimited

13. SUPPLEMENTARY NOTES**14. ABSTRACT**

More than 50 hours of TODWL data from both the Monterey and DPG areas has been processed. We are continuing efforts to combine the information from the TODWL, CTV and Twin Otter sensors to establish the relationship between the local fluxes and the energetics of LLJs and OLEs. Effort has also continued on modifying the EDMF parameterization to account for the differences between thermally driven convection and dynamically driven vertical transports.

We continue to modify the EDMF parameterization to account for the differences between thermally driven convection and dynamically driven vertical transports.

15. SUBJECT TERMS

OLE, EDMF, Doppler Wind Lidar
